Abstract

In mobile environment, nodes can move around and voluntarily leave or join the network. Furthermore, they can crash or be disconnected from the network due to the absence of network signals. Therefore, failure, disconnection and mobility may create partitions in wireless networks which should be detected for fault and disconnection tolerance reasons.

We present in this article an architecture of local and distributed detectors for mobile networks that detect failures, disconnections, and partitions. It is basically composed of three unreliable detectors: a heartbeat failure detector, a vector-based disconnection detector, and an eventually perfect partition detector.

1. Introduction

Recent advancements in wireless data networking and portable information appliances have given rise to the concept of mobile computing. Users can access information and services irrespective of their movement and physical location. However, such an environment is extremely dynamic: Nodes can voluntarily disconnect themselves or move around; absence of wireless network signals can disconnect nodes from the network; nodes can fail and messages can be lost. Consequently, failure, disconnection, or mobility may cause a node or several of them to detach from the rest of the network, creating one or more network partitions. Another particularity of mobile environment is the fact that links are not bidirectional because, in practice, the two processes cannot rely on the same physical and logical resources in both directions. For argument’s sake, small devices like PDAs consume more power energy for emitting than for receiving messages on wireless networks, thus leading to non-uniform radio range.

As the geographic extent of the system grows or its connectivity weakens, network partitions tend to be more frequent. They may result in a reduction or degradation of services but not necessarily render the application completely unavailable. Partitions should keep working as autonomous distributed systems offering services to their clients as far as possible. Algorithms that should benefit from a partition detector module are for instance distributed consensus in partitionable networks, and resources allocation and placement in dynamic networks. Therefore, a mechanism for providing information to the application about network partition is highly important in wireless environments, and is the focus of this paper. We propose an eventually perfect unreliable partition detector for wireless systems. Similarly to an unreliable failure detector [5], an unreliable partition detector can be considered as a per process oracle, which periodically provides, for each process $p$, a list of processes suspected to be unreachable, that is those processes which are suspected of being in another partition than $p$’s one. A partition detector is unreliable in the sense that it can make mistakes. Two properties characterise a failure detector: completeness and accuracy. Roughly speaking, completeness sets requirements in respect to crashed processes, while accuracy restricts the number of false suspicions. By analogy, these two properties also characterise our partition detector, but with respect to reachable processes. Thus, our partition detector assures the following completeness and accuracy properties: A process $p$, which is correct, eventually detects every process that does not take part in $p$’s partition; and $p$ eventually stops suspecting correct processes that belong to its partition.

Our partition detector is able to detect partitions due to disconnections as well as failures. The ultimate goal
of characterising the nature of the partition is to help the
decision-making process of applying countermeasures for
fault tolerance and disconnection tolerance: e.g., remove
a faulty participant from a vote and wait for disconnected
ones. Hence, in order to build our partition detector, a fail-
ure detector and a disconnection detector are required. Both
detectors participate in our solution and the partition detec-
tor exploits information provided by them.

In our approach, we consider that there is a local con-
nectivity module at each mobile node which is responsible
for informing whether that node can send messages or not [9]. It monitors resources such as energy power, mem-
ory space and wireless link quality by controlling one of
their attributes such that, when the raw value of the attribute
is below some threshold, the mobile node is disconnected.
The objective of a connectivity module is to establish a con-
nectivity mode (from strongly connected to disconnected)
in a stabilised manner. However, such connectivity infor-
nation needs to be spread over the network. Hence, when a
node is locally notified of its disconnection, the disconnec-
tion detector that we propose will “try” to spread the dis-
connection information over the network, through its neigh-
bours, by calling the broadcast primitive mentioned above.

The contribution of our paper is then threefold: (1) a
modified version of the HB failure detector of [1, 2] which
besides offering information about failure suspicions and
the possibility of building a quiescent stubborn reliable
broadcast primitive, provides information about the reacha-
bility of nodes; (2) an unreliable disconnection detector that
broadcasts disconnection information through the network;
and (3) an eventually perfect partition detector that, based
on the information given by the two previous detectors, de-
tects network partitions.

The remainder of this paper is organised as follows. In
Section 2, we set out the distributed system model. Sec-
tion 3 presents our global architecture and the basic primi-
tives used throughout the paper. Section 4 describes the
heartbeat failure detector for partitionable networks with
terminal mobility and explains how the original algorithm
was modified. The disconnection detector is presented in
Section 5, and the partition detector in Section 6. We com-
pare our contribution with related work in section 7 while
section 8 concludes our work.

2. Distributed System Model

We consider a partially synchronous distributed system
in which there are bounds on process speeds and on mes-
sage transmission delays, these bounds are unknown, but
they hold after some unknown time, which is called GST
for Global Stabilisation Time [5]. The system consists of
a set of n processes Π = {p1, p2, ..., pn}. The network of
processes is a directed graph G = (Π, Λ) where Λ ⊂ Π×Π.

The topology of the graph changes due to node movements
and node failures, but the set of participants Π to the dis-
tributed application is known. Without lack of generality,
we assume that there is one process per mobile terminal.
Process q is a neighbour of process p if and only if there is
an unidirectional link from p to q.

Failure model Processes and links can fail by crashing,
that is by prematurely halting and then stopping performing
any further action for ever. During the execution, by defi-
nition, processes and links that have not crashed are said to
be correct. In addition, correct links are fair lossy. A fair
(lossy) link may lose messages, but if a process p repeatedly
sends a message m to process q, then q eventually receives
m.

Disconnection model Processes can disconnect and
reconnect. In connected mode, a process may send a mes-
sage to its neighbours, while in disconnected mode, the re-
sources of the process terminal are too low to send any ap-
plication message but control messages may be transmitted
for a while. We assume that every process ends its execu-
tion while being connected and does not crash while being
disconnected. In practice, the assumption means that the
disconnected, and then terminating or faulty process does
not succeed in leaving the set of participants Π. Then, a
mechanism of leases at the application level will make the
incriminated process leaving the set of participants. In the
sequel, this translates into the assumption that a terminal
that disconnects eventually reconnects. A moving node first
disconnects from the network then it moves to a new loca-
tion and finally reconnect to the network. We assume that
mobile terminals eventually stop moving.

Partition model Following the terminology given in [1,
2], the network is said to be partitionable, that is a network
in which some links may be unidirectional and may crash.
By definition, a fair path between processes p and q is a
path containing only fair links and correct processes, and
a simple fair path is a fair path in which no process ap-
pears more than once. In addition, process q is said to be
reachable from process p if there exists a fair path between
p and q, otherwise it is unreachable. p and q are mutually
reachable if there exists a fair path between p and q, and a
fair path between q and p. Then, the p’s partition, denoted
partition(p), is the set of correct processes mutually reacha-
ble by process p.

1Note that we consider that when a node disconnects, it disconnects
from all the nodes, not only from a particular node. The topology changes
are gathered in the concept of neighbourhood.
3. Unreliable detection modules and basic communication primitives

On each node, we provide a basic layer ($BL$). The function of this layer is twofold. First, it establishes a connectivity mode (from strongly connected to disconnected) in a stabilised manner. Secondly, it provides a list of current neighbours ($nghset$) by periodically calling the networking layer. By analogy with the participant detector of [4], the neighbourhood detector does not make any mistake: It is perfect. The very reason is that we can’t verify whether logical connections are correctly managed, or whether network configuration data are correct. For instance, if the underlying operating system makes a mistake, the mobile terminal will find the links faulty (false positive) or will not use opened connections (false negative). Each change in mode and $nghset$ is notified to the upper layers.

On each node $p$, two detectors are plugged onto $BL$: The heartbeat failure detector ($HBFD$) and the vector-based disconnection detector ($VBDD$). $HBFD$ outputs a vector $HB$ of heartbeat counters, one entry per process, and a set of mutually reachable processes $mreachable$. $VBDD$ outputs a vector $de$ of disconnection counters, one entry per process. Disconnections and (re-)connections are numbered: Disconnection events are odd-numbered and reconnection events are even-numbered.

At the upper level of node $p$, the eventually perfect partition detector $EPPD$ uses information provided by both $HBFD$ and $VBDD$ to compute the set $out$, that is the set of processes not in $p$’s partition. Based on $HBFD$, we provide a quiescent stubborn broadcast primitive $QSB$ used by $VBDD$ to broadcast disconnection and reconnection information.

$HBFD$, $VBDD$ and $EPPD$ are characterised by both completeness and accuracy properties defined as follows:

- **$HB$-Completeness**: At each correct process $p$, the heartbeat counter of every process not in $partition(p)$ is bounded.
- **$HB$-Accuracy**: At each correct process $p$, the heartbeat counter of every process is nondecreasing. The heartbeat counter of every process in $partition(p)$ is unbounded.
- **$VBDD$-Completeness**: Eventually all disconnections and reconnections of correct process $p$ are seen by every correct process in $partition(p)$.
- **$VBDD$-Accuracy**: No process sees a disconnection (resp. reconnection) before the disconnection (resp. reconnection) effectively occurs.
- **$EPPD$-Completeness (Strong partition completeness)**: If some process $q$ remains unreachable from a correct process $p$, then eventually $p$ will always suspect $q$ of not belonging to $partition(p)$.
- **$EPPD$-Accuracy (Eventual strong partition accuracy)**: If some process $q$ remains reachable from a correct process $p$, then eventually $p$ will no longer suspect $q$ of not belonging to $partition(p)$.

Each process can use the following primitives to communicate:

- **$send(\text{dest}, m) / receive(\text{from}, m)$**: Two basic point-to-point communication functions to send (resp. receive) message $m$ to (resp. from) its neighbour $\text{dest}$ (resp. $\text{from}$. When information is locally exchanged between local detectors, $local_send(\text{dest}, m)$ and $local_receive(\text{from}, m)$ functions are used where $\text{from}$ and $\text{dest}$ are the name of the component ($HBFD$, $VBDD$, or $BL$).
- **$broadcast(m)$**: This function called $QSB$ broadcasts message $m$ over fair links to all the correct processes in the partition of the correct sender. This primitive provides the abstraction of stubborn links hiding the retransmission mechanisms used to make somewhat reliable the transmission of messages. A formulation of the stubborn delivery property is as follows [7]: If the sender $p$, which does not crash, sends a message $m$ to $q$ that is correct, and $p$ is able to indefinitely delay the sending of any further message, then $q$ eventually receives $m$. An important practical consideration is that stubborn links require only a bounded buffer space (minimum of one message). The quiescence property ensures that only a finite number of messages are sent when broadcast is invoked a finite number of times, even if processes involved in broadcasting move to other partitions (only a finite number of messages are sent in the latter partitions). $QSB$ uses $HBFD$. Due to the lack of space, we do not present the broadcast algorithm in this paper; the algorithm is a direct modification of the quiescent broadcast primitive given in [2] (Figure 3) in order to add the stubborn property as presented in [7].

4. Failure detection

Our failure detector $HBFD$ is based on the class of heartbeat failure detectors proposed by [1, 2]. Such a choice is firstly explained by the need to build quiescent algorithms, that is algorithms that eventually stop sending messages in partitionable networks. In [2], the authors prove that quiescent reliable communication are impossible with classical failure detectors whose implementation provides output of bounded size (e.g., the list of suspects has bounded
Heartbeat failure detectors provide for each process $p$ a vector of counters $HB = [n_1, n_2, ..., n_k]$ where each $n_j$ is a positive integer corresponding to the number of heartbeats received by process $p$ from process $p_j$. Thus, $n_j$ is the “heartbeat value of $p_j$ at $p$”. Intuitively, $n_j$ increases as long as $p_j$ is correct, not disconnected, and in partition($p$). Notice that heartbeat failure detectors provide the vector $HB$ without any treatment or interpretation. Then, other detectors, as our partition detector $EPPD$, can periodically obtain the current value of $HB$ vector from $HBFD$ in order to deduce lists of suspected processes.

Aside the heartbeat vector $HB$, our failure detector $HBFD$ gives information about the topology of the network since each process keeps information about which processes can be reachable through its neighbours. For each neighbour $r$ of process $p$, $HBFD$ builds the set of processes mutually reachable from $p$ through $r$. This set is called the reachability set of $p$ through $r$ and the vector $mreachable$ gathers the set of reachability sets of all the neighbours of $p$. The property of mutual reachability can be expressed as follows: At each correct process $p$, for each neighbour $r$, the reachability set for $r$ ($mreachable[r]$) eventually contains all the correct processes (e.g., $q$), such that there is a simple fair path from $p$ to $q$ through $r$ and a simple fair path from $q$ to $p$. Furthermore, $HBFD$ can also accept requests for emptying some of the reachability sets in order to restart an accumulation phase of topology discovery. This functionality is used by our partition detection $EPPD$, described in Section 6, when a failure or a disconnection is detected.

$HBFD$ which runs on each node $p$ is presented in Algorithm 1. It is based on the algorithm for partitionable networks described in [1]. The changes we have made are related to the addition of nodes mobility and the discovery of the network topology through neighbours. The variables $HB$ and $mreachable$ respectively store the per process heartbeat counters and the per process mutual reachability sets, as previously described. The set $ nghbrs$ controls the current neighbours of $p$, while the set $paths$ gathers all the paths of which $p$ is aware since its last heartbeat sending. Algorithm 1 is executed by process $p$ ($p \in \Pi$), and it is divided into five parallel tasks. It provides to the upper client, e.g. the partition detector $EPPD$, the heartbeat vector $HB$ and the reachability sets (sets of $mreachable$) (line 16). The principle of the algorithm is the piggy-backing of fair paths in heartbeat messages.

The first task (lines 1–5) corresponds to the code block executed at the creation of the heartbeat failure detector. The second task (lines 6–9) is triggered when the neighbourhood changes. Such an information, nghset, is provided by $BL$ (cf. Section 3). This task controls the mobility of nodes and therefore the current set $ nghbrs$ of neighbours of $p$ (line 9). Furthermore, the entries of $mreachable$ corresponding to those processes that are no longer neighbours of $p$ are set to empty (line 7) since they cannot be reached anymore from $p$ through old neighbours. However, new neighbours of $p$ are seen as reachable (line 8).

**Algorithm 1: Heartbeat Failure Detector $HBFD$**

```plaintext
upon initialisation do
  nghbrs ← ∅
  HB[1..|Π|] ← {0, ..., 0}
  mreachable[1..|Π|] ← {∅, ..., ∅}  \( p \) reach. through neigh. from \( p \)
  paths ← ∅  \( p \) set of paths received in heartbeats during last period of time
  upon local_receive($BL$, nghset) do
    for all $q \in nghbrs \setminus nghset$ do mreachable[$q$] ← ∅
    for all $q \in nghset \setminus nghbrs$ do mreachable[$q$] ← {q}
    nghbrs ← nghset
  periodically do
    $HB[p] ← HB[p] + 1$
    paths ← paths ∪ \{\{p\}\}
    for all $p \in paths : (\exists r \in path : r \text{ appears more than twice in } path)$ do
      paths ← paths \ path
    for all $q \in nghbrs \setminus nghset$ do send($q$, ($HBFD$, paths))
    paths ← ∅
    local_send($EPPD$, ($HBFD$, HB, mreachable))
  upon receive($q$, ($HBFD$, pathsq)) do
    for all $p \in pathsq$ do
      for all $r \in \Pi : \exists r \in path : HB[r] \rightarrow HB[r] + 1$
      if $\exists r \in \Pi : r \text{ appears right next to } p \text{ in } path$ then
        for all $s \in \Pi : s \text{ appears after } r \text{ in } path : mreachable[r] ← mreachable[r] \cup \{s\}$
      endif
      paths ← paths ∪ \{(path . p)\}
    endfor
  upon local_receive($EPPD$, ($EPPD$, procset)) do
    for all $s \in procset$ do mreachable[$s$] ← ∅
```

In the third task (lines 10–16), process $p$ periodically increments its own heartbeat and adds itself to $paths$, which already contains all paths received in heartbeat messages during the last period of time. However, before sending to all its neighbours a new heartbeat message which includes such a variable (line 14), $p$ verifies in line 13 if its previous heartbeat messages have not already completed two cycles. In this case, such a path will be removed from $paths$ (line 13). As shown in the example of the execution of the algorithm described below, some topology requires that heartbeat messages complete two cycles in order to ensure that processes correctly update their mutually reachable sets. At the end of the third task, the heartbeat failure detector notifies its clients, $EPPD$ in our case, about new updated information concerning the heartbeat vectors and reachability sets (line 16).

The fourth task (lines 17–24) handles the reception of messages by $p$ of the form ($HBFD$, $paths$). Upon receiving it from process $q$, for each $path \in paths$ with $path = \{(p_1 \rightarrow \cdots \rightarrow p_i \rightarrow p \rightarrow p_j \cdots \rightarrow p_k \rightarrow q)\}$, $p$ adds the processes $(p_1 \cdots p_i \rightarrow p_q \rightarrow q)$, which appears after its neighbour $r$, to $mreachable[r]$ (lines 20–21). Therefore, $mreachable[r]$ contains a list of processes that can be mutually reached from $p$ through $r$. In addition, process $p$ increases the heartbeat counters of
all the processes that appear after \( p \) in \( \text{path} \), that is all the processes of the sequence \((r \cdot p_2 \cdots p_k \cdot q)\) (line 19), since they are not suspected by \( p \). Process \( p \) appends then itself to \( \text{path} \) and stores the new path in \( \text{paths} \) (line 23). Notice that in this case, \( p \) is also reachable from \((p_j \cdots p_k \cdot q)\) through their respective neighbours.

Finally, the fifth task (lines 25–26) empties some entries of \( \text{mreachable} \). As previously explained, this functionality is used by the partition detector \( \mathcal{EPPD} \), described in section 6.

**Example of execution of \( \mathcal{HBPFD} \)** In order to explain how nodes dynamically discover which are the other nodes reachable through their respective neighbours, we show in Figure 1 the scenario of an execution of Algorithm 1, considering a topology with five nodes.

Node 1 starts by sending to its neighbour node 2 a heartbeat message that contains the variable \( \text{paths}_1 \), which, in this case, includes just itself, as shown in Figure 1.(a) (line 12). Upon receiving it (cf. Figure 1.(b)), node 2 appends itself to all the received paths, adding the latter to its variable \( \text{paths}_2 \) (line 23). Notice that it does not update its variable \( \text{mreachable}_2 \) since it is not included in any of the received paths. Next, the set \( \{2\} \) is being added to \( \text{paths}_2 \) (line 12) and a new heartbeat message is sent to its neighbours. Both nodes 1 and 3, outgoing neighbours of 2, receive it.

In Figure 1.(c), both nodes 1 and 3 receive the above heartbeat message, while in Figures 1.(d) and 1.(e), node 4 receives the heartbeat messages sent by node 3, and node 5 receives the heartbeat messages sent by node 4, respectively. Next, when node 2 receives the heartbeat message from node 5 (cf. Figure 1.(f)), it finds itself in some of the received paths. Therefore, line 21 of the algorithm is executed and node 2 adds nodes 4 and 5 to \( \text{mreachable}_2 \), that is these nodes are mutually reachable from node 2 through its neighbour node 3.

Finally, Figure 1.(g) shows that the content of variable \( \text{paths}_1 \) of node 1 after having received the second heartbeat message from node 2. In the scenario, we consider that node 1 has not sent any new heartbeat message after the reception of the first heartbeat message from node 2. Node 1 then updates its variable \( \text{mreachable} \) (\( \text{mreachable}_1 \) = \( \{2, 3, 4, 5\} \)) since these nodes appear after its neighbour 2 in path \( \{1, 2, 3, 4, 5, 2, 1\} \).

**Sketch of proof** \( \mathcal{HBP} \)-completeness: The proof is by contradiction. Let \( q \) be a process that is not in the partition of \( p \) (\( p \neq q \)). Assumes that \( \mathcal{H}B[q] \) is not bounded. Then, \( p \) receives an infinite number of times messages \( \langle \mathcal{HBPFD}, \text{paths} \rangle \), where there exists a path \( P \) in \( \text{paths} \) which contains \( q \) after \( p \). This path is of the form \( P = (p_1 \cdots p \cdots q \cdots p_k) \). Since \( p \) receives an infinite number of messages from \( p_k \), the link \( p_k \rightarrow p \) is fair. By repeated application, for each \( j = k - 1, \ldots, 1 \), the link \( p_j \rightarrow p_{j+1} \) is fair. Thus, in \( P, (p \cdots q) \) is a fair path from \( p \) to \( q \) and \( (q \cdots p_k \cdot p) \) is a fair path from \( q \) to \( p \). Therefore, \( p \) and \( q \) are in the same partition — a contradiction.

\( \mathcal{HBP} \)-accuracy: The first part (the heartbeat counter of every process is nondecreasing) is obvious since \( \mathcal{HB}[q] \) can only be changed in lines 11 and 19. For the second part (the heartbeat counter of every process in the partition of \( p \) is unbounded), two cases are possible. Let \( q \) be a process in the partition of \( p \). If \( q = p \), then line 11 is executed infinitely often (since \( p \) is correct) and \( \mathcal{HB}[p] \) is unbounded. Now, assume \( q \neq p \) and let \( (p_1 \cdots p_k) \) be a simple fair path from \( p \) to \( q \), and \((p_1 \cdots p_k) \) be a simple fair path from \( q \) to \( p \) so that \( p_1 = p_k = p \) and \( p_i = q \).

For \( j = 1, \ldots, k - 1 \), let \( P_j = (p_1 \cdots p_j) \). By induction on \( j \), we can show that, for each \( j = 1, \ldots, k - 1 \), \( P_j \) sends messages \( \langle \mathcal{HBPFD}, \text{paths} \rangle \) to \( p_{j+1} \) an infinite number of times, where there is a path \( P \) in \( \text{paths} \) such that \( P = \text{subpath} \cdot P_j \). For \( j = k - 1 \), this claim shows that a neighbour of \( p \) sends messages \( M = \langle \mathcal{HBPFD}, \text{paths} \rangle \) to \( p \) an infinite number of times, where there is a path \( P' \) in \( \text{paths} \) such that \( P' = \text{subpath} \cdot P_{k-1} \). Since \( p \) is correct and by the fairness property of the links, \( p \) receives messages of the form of \( M \) an infinite number of times. Since \( q \) appears after \( p \) in \( P_{k-1} \), \( \mathcal{HB}[q] \) is incremented an infinite number of times (line 19). Therefore, \( \mathcal{HB}[q] \) is unbounded.

### 5. Disconnection detection

The connectivity information provided by \( \mathcal{BC} \) (cf. Section 3) remains local to the mobile node. Hence, as we want in our approach to make the difference between a disconnection and a failure, the disconnection/reconnection information of nodes should be spread over the network.

We consider that when a node is disconnected from the network, its does not send application messages anymore. However, this does not mean that control messages sent by fair links cannot be transmitted; in other words, physical transmission may be still possible for a while. Contrary to failures which are unexpected, there is a lapse of time between the connectivity detection of the node “disconnected” and the effective physical disconnection. Such a lapse of time can be used for alerting remote processes of a node disconnection. Clearly, in the case of a sudden disconnection, no disconnection message can be sent and the disconnection will be detected as a failure by the failure detector that runs on correct and connected processes. This false suspicion will last for the duration of the disconnection and will be corrected when the disconnected process reconnects. On the other hand, in the case in which the end-user disconnects themselves voluntarily, we consider that the middleware service responsible for isolating the user’s node
waits for a short while before actually performing the disconnection, thus allowing the transmission of control messages before the interruption of communication.

Then, we introduce the concept of unreliable vector-based disconnection detector, \textit{VBDD}, similar to the one of unreliable failure detection. When a process is notified of a disconnection either by \textit{BL} or voluntarily by the end-user, \textit{VBDD} “tries” to transmit the disconnection information to all the processes by calling \textit{QSB}. \textit{VBDD} builds thus a coherent distributed view of disconnection events.

By analogy with heartbeat failure detectors, the disconnection detector does not output a list of disconnected processes, but provides a per process vector, named \textit{dv}, of disconnection/reconnection event counters. If \textit{dv}[q] of process \textit{p} contains an even value, \textit{q} is considered to be seen as connected by \textit{p}, otherwise it is considered to be disconnected. Notice that such an interpretation of the disconnection vector’s entries is done afterwards by the partition detector \textit{EPPD}. It is worth mentioning that \textit{VBDD} considers only disconnection/reconnection of correct processes. Indeed, by construction, the disconnection detector is not able to suspect processes of being faulty. So, as mentioned in Section 2, we assume that every process does not crash while being disconnected.

The algorithm for process \textit{p} of our disconnection detector \textit{VBDD} for partitionable networks which supports node mobility is presented in Algorithm 2. It has four tasks. The principle of the algorithm is to broadcast via \textit{QSB} the disconnection vector \textit{dv} into \textit{VBDD} messages when one of the following events is triggered: New neighbourhood, voluntary disconnection, connectivity mode change, or delivery of a \textit{VBDD} message with new information. The local vector \textit{dv} keeps information about process disconnection/reconnection, as previously described. The local variable \textit{voluntaryDisc} indicates whether the end-user has requested a voluntary disconnection, and \textit{mode} is a variable which is updated with the information provided by \textit{BL} about the connectivity of node \textit{p} itself, the latter information being inferred from raw data from the execution context. Thus, by considering the information about both voluntary disconnection and local connectivity, \textit{VBDD} infers the logical connectivity of \textit{p}, which it stores in \textit{dv}[\textit{p}].

The first task (lines 1–4) corresponds to the code block executed at the creation of the disconnection detector. Every process is considered to be connected at the beginning of the execution (lines 2–4). The next task (lines 5–10) allows the end-user to voluntarily disconnect or reconnect (by opposition to involuntary disconnections or reconnections detected by \textit{BL}). The assignment of the variable \textit{voluntaryDisc} (line 6) is followed by the propagation of this new disconnection event to every neighbour (line 9). Naturally, voluntary disconnections outdo involuntary disconnections/reconnections. Thus, when \textit{p} is not already disconnected, either voluntarily or involuntarily (\textit{mode} $\neq$ ‘d’), a voluntary disconnection effectively disconnects the process. Similarly, when \textit{p} is currently voluntarily disconnected and involuntarily connected (\textit{mode} $\neq$ ‘d’), a voluntary reconnection effectively reconnects the process. The third task (lines 12–18) is executed when there is a change in the connectivity mode which is detected by \textit{BL}.
node becomes disconnected or connected, and the end-user did not ask for a voluntary disconnection (condition of the if at line 13), p broadcasts the new disconnection event (line 15).

The last task (lines 19–24) is responsible for the updating of the disconnection vector as a result of the delivery of a newly-received disconnection vector (dvq), contained in a VBDD message. At line 20, dv is compared with dvq. If one or more of the values of dv entries are smaller than the dvq’s ones, dv is updated with the maximum of the entries of the two vectors (line 21) and dv is broadcast (line 22). This new disconnection message is going to update the disconnection vector of other processes that might not be aware of some disconnection/reconnection events. At p, VBDD then provides to the upper detector EPPD, which runs on p, the disconnection vector dv (line 23).

**Algorithm 2: Vector-based disconnection detector VBDD**

1. initialization do
2. dv[1..|Π|] ← {0, ..., 0} [Vector of disk sequence numbers at p]
3. voluntaryDisc ← false [true if voluntary disconnection of p]
4. mode ← c' [connectivity mode at p]
5. upon voluntary disconnection/reconnection by the end user do
6. voluntaryDisc = voluntaryDisc
7. if mode ≠ 'd' then
8. dv[p] ← dv[p] + 1
9. broadcast(VBDD, dv)
10. local_send(EPPD, VBDD, dv)

23. local_send(EPPD, VBDD, dv)
24. endif

**Sketch of proof** VBDD-completeness: In the following, the generic expression “disconnection event” is used to refer to all VBDD messages. There are four possible cases: (1) p successfully sends a VBDD message to all its neighbours; (2) p is physically disconnected just before sending a VBDD message; (3) p successfully sends the disconnection event to at least one correct and connected process q; and (4) p moves. In the first case, by the stubborn delivery property (Section 3 page 3), all the correct processes in partition(p) eventually deliver a VBDD message containing a disconnection vector greater than or equal to dv. In the second case, the VBDD message is sent whenever p reconnects. This is because of the properties of the stubborn primitive: Messages are saved in the mobile terminal’s buffer and are sent when the terminal reconnects. p then successfully disseminates this message or a newer one as done in the first case. In the third case, if q is not physically disconnected after delivering the disconnection event of p, then it successfully disseminates this event as done in the first case. But, if q is physically disconnected right after the delivery of the VBDD message of p, again, the disconnection event or a newer one is disseminated whenever process p or q reconnects to the network, as in the second case. Finally, if q successfully transmits the disconnection event to at least one of its neighbours, this is again the third case by recursion. Clearly, by the stubborn delivery property, a VBDD message containing dv or a greater dv is eventually delivered by all the correct processes in partition(p). In the last case, neighbourhood changes provoke the broadcasting of a VBDD message to the new neighbourhood. Clearly, the decomposition into the first three cases just studied before is also valid, leading to the same conclusion.

**VBDD-accuracy** First of all, notice that the pth entry of the disconnection vector is only incremented at process p when p executes the code statements corresponding to voluntary disconnections/reconnections (line 5) or to involuntary disconnections/reconnections (line 12). Next, other processes update the pth entry of their disconnection vector only when treating VBDD messages. Therefore, the pth entry of the disconnection vector of process q (q ≠ p) is always less than or equal to the pth entry of the disconnection vector of p.

### 6. Partition Detection

A network can become partitioned due to link or node failures as well as node disconnections. In this section, we present a generic partition detector EPPD, which establishes, for process p, the set of suspected processes which are not in partition(p). To this end, EPPD exploits information given by both HBFD and VBDD.

EPPD has been defined based on the completeness and accuracy properties as described in Section 3. Its specification is inspired from [3], where a failure detection for partitionable group systems is presented. The authors formalise the stability conditions that are necessary for solving group membership in asynchronous systems. The specification is close to our approach because it is expressed by the reachability between pairs of processes rather than on individual processes being correct or crashed. Considering process p, EPPD suspects those processes that do not belong to the same partition of p. However, it provides a list of suspected processes only for stabilised periods. Thus, the objective of EPPD is to allow algorithms, adapted for partitionable networks, to terminate their execution with a smaller number of processes during stabilised periods, that is during which partitions stabilise.

Algorithm 3 describes our partition detector EPPD. It tries to discover network partitions using both the heartbeat vector and reachability information provided by HBFD, as
well as the disconnection vector provided by VBDD. All local variables are initialised in the first task (lines 1–5). The set of suspected processes that do not belong to the same partition of p is noted as out (for “out” of the partition). Hence, in order to be able to provide such a set, we have introduced a time-out, which allows to build an eventually perfect detector based on heartbeat vector values given by HBFD (see variables HB and prevHB). At the same time, the reachability information is stored in variable mreach. EPPD also parses disconnection vectors provided by VBDD (see variable dv).

Algorithm 3: Eventually Perfect Partition Detector EPPD

1. upon initialisation do
2. out ← ∅ (processes suspected to be out of partition(p))
3. mreach ← {∅, ..., ∅} (mutually reachable sets)
4. prevHB[p][1]|Π| ← {0, ..., 0} [previous heartbeat counters]
5. prevDV[p][1]|Π| ← {0, ..., 0} [previous disconnection vector]
6. upon local_receive(VBDD, (VBDD, dv)) do
7. for all q ∈ Π : prevDV[q] < dv[q] do
8. if dv[q] mod 2 = 1 then [new disconnection]
9. call add(q)
10. else call remove(q) [new reconnection]
11. endfor
12. endfor
13. endfor
14. upon local_receive(HBFD, (HBFD, HB, mreachable)) do
15. mreach ← mreachable [new mutually reachable sets]
16. for all q ∈ Π : q ≠ p do
17. if HB[q] − prevHB[q] < 1 ∧ q ∉ out then [failure suspicion]
18. call add(q)
19. local_send(HBFD, (EPPD, out))
20. else if HB[q] − prevHB[q] ≥ 1 ∧ q ∈ out ∧ dv[p] mod 2 = 0 then
21. call remove(q) [false suspicion]
22. local_send(HBFD, (EPPD, out))
23. endfor
24. endfor
25. endfor
26. procedure add(q)
27. out ← out ∪ {q}
28. if q = p then out ← Π \ {p} [local disconnection]
29. else [disconnection or failure of a remote process]
30. for all s ∈ Π : s ∈ mreach[q] ∧ s ≠ q ∧ dv[s] mod 2 = 0 do
31. if dv[s] ∈ Π : s ∈ mreach[q] ∧ s ≠ q ∧ dv[s] mod 2 = 0 ∧ s ∈ mreach[s] then
32. out ← out ∪ {s}
33. endfor
34. endelse
35. procedure remove(q)
36. out ← out \ {q}

The second task of EPPD (lines 6–13) monitors the disconnection events received from VBDD. Each entry of the disconnection vector is analysed. When VBDD at process p notifies a new disconnection of process q, all processes considered not to be reachable anymore from p due to the disconnection of q, are added to out by the call of the procedure add at lines 26–33. The latter procedure parses the reachability sets to detect which are the processes that became unreachable from p, that is processes that are no more reachable through any neighbour of p. Then, in order to forget those processes that were previously reachable from p through q (when q was a neighbour of p), the reachable set mreach[q] is reset. This is done by sending a message to the local HBFD (line 11). On the other hand, when the event notified by VBDD is a new reconnection of q, that is q is no more suspected to be unreachable from p, q is removed from out (procedure remove at lines 34–35).

The last task (lines 14–25) monitors failure by examining both the heartbeat counters and reachability sets provided by HBFD. For each process in Π, the difference between the values of the new heartbeat counter HB and the old heartbeat counter prevHB is compared against the failure detection threshold value 1. In the test of line 17, a failure suspicion of process q detected at process p is new if (1) p suspects q (HB[q] − prevHB[q] < 1), and (2) q is not already suspected (q ∉ out). In this case, process q and all the processes that became unreachable from p due to the failure suspicion of q are added to out by the call of the procedure add. Contrariwise, a false suspicion of process q detected at process p (line 20) is new if (1) p does not suspect q (HB[q] − prevHB[q] ≥ 1), (2) q is already suspected (q ∈ out), and (3) p is not seen as disconnected. In this case, q is removed from out by the call to the procedure remove (lines 34–35).

Sketch of proof  Strong partition completeness: There are 3 cases to consider: q is included in out (1) either due to the disconnection detection of q, (2) or due to the failure suspicion of q, (3) or even due to the partition suspicion of q following the disconnection or the failure of another process r. In the first case, from the VBDD-completeness property, we know that the corresponding disconnection event of q is eventually delivered by every correct process in partition(p). Thus, all the correct processes in partition(q) execute the code block at lines 6–13, and q is added to the set out. In the second case, from the HB-completeness property, we know that the heartbeat counter of every process q ∉ partition(p) is eventually bounded. Thus, for all the processes in partition(p), the condition at line 17 is eventually true and q is added to the set out. The third case, the partition suspicion of q due to the disconnection detection or the failure suspicion of another process r, is included in the previous cases. Process q is added to the set out by the call of the procedure add at lines 29–31.

Eventual strong partition accuracy: The proof is by contradiction. Assume a correct process q ∈ partition(p) is permanently suspected by p, that is q ∈ out. From the HB-accuracy property, we know that the heartbeat counter of every process in partition(p) is unbounded. In addition, from the VBDD-accuracy property and since q ∈ partition(p), q is connected. Therefore, the condition of the test at line 20 is eventually true and q is eventually removed from the set out—a contradiction.

7. Related work

The failure detector presented in this paper is based on seminal work on heartbeat failure detectors by Aguilera,
Chen and Toueg [1, 2]. The distributed system model is the same and is suitable for mobile ad hoc networks: A partially synchronous model, that is an asynchronous model augmented with failure detection for partitionable networks. Even if not mentioned in their papers, heartbeat failure detection algorithms are inherently convenient for tolerating nodes mobility. We have added a neighbourhood detector that notifies topology changes of the neighbourhood, and modified the transmission and the parsing of paths in heartbeat messages in order to (1) let the heartbeat message return to the initiator even if the path includes a cycle and to (2) build the set of processes reachable through neighbours.

In the literature, few unreliable failure detectors explicitly target mobile ad hoc networks. In [6], the authors propose an adaptation of a gossip-based failure detector. Heartbeat messages are logically stamped, and a vector clock is piggybacked in every heartbeat message. In order to tolerate nodes mobility, the failure detector algorithm allows gaps of some heartbeats between adjacent heartbeat arrivals. Contrary to our distributed model, the links are bidirectional.

In [8], an architecture for local failure detection that tolerates terminal mobility is presented in the context of sensor networks. The distributed model assumes that every process uses the same time unit. The mobility is said to be passive, that is nodes are not aware they are moving and the network does not partition. In our work, the distributed model is weaker, but assumes that each node is equipped with a neighbour detector. We do not build such neighbour detector but claim that network protocols can provide such information. Furthermore, in [8], the architecture is built around a local failure detector (correct processes eventually only suspect processes in the local neighbourhood) and mobility detection layer. The local failure detection is implemented using any $\diamond P$ algorithm, not provided in the paper. The mobility detection algorithm is a periodic gossip broadcasting computation with one initiator and with termination detection.

Concerning disconnection detection, to the best of our knowledge, there is no deterministic algorithm in the literature. Concerning partition detection, [3] discusses the property of a failure detector for partitionable group communication systems, but the authors do not give any implementation. Our partition detector is inspired by this specification. In addition, contrary to [3], in our proposition, communication channels can be unidirectional. Finally, we see our partition detector as the participant detector introduced in [4]: The set of participants is the set of reachable processes and the consensus is re-launched when the partition changes. Our neighbourhood detector conforms to the information accuracy property of the participant detector. The second property, namely information inclusion, is not present in our proposition because the set of potential participants $\Pi$ is assumed to be known in our model.

8. Conclusion

This paper has presented a derived version of a heartbeat failure detector in which the paths of processes piggybacked in the heartbeat messages are also parsed to build a topology of the network reachable through the neighbours. The failure detector tolerates the mobility of the processes, and then topology changes. Since disconnections are frequent in mobile ad hoc networks, and in order to make the distinction between failures and disconnections, the paper has also introduced the concept of unreliable disconnection detection and has presented a vector-based disconnection detector. Our disconnection detector take advantage of a quiescent stubborn broadcast primitive to broadcast disconnection information whenever possible, that is optimistically. The hints provided by the heartbeat failure detector and by the vector-based disconnection detector are interpreted by an eventually perfect unreliable partition detector for wireless systems subject to node and link crashes, and subject to nodes mobility. The partition detector outputs for each process $p$ a list of processes suspected to be unreachable, that is those processes which are suspected of being in another partition than $p$’s one.
