Self-stabilization
Shared memory
Message passing
Single writer multiple reader register

\textbf{A B S T R A C T}

A fault-tolerant and practically stabilizing simulation of an atomic register is presented. The simulation works in asynchronous message-passing systems, and allows a minority of processes to crash. The simulation stabilizes in a practically stabilizing manner, by reaching a long execution in which it runs correctly. A key element in the simulation is a new combinatorial construction of a bounded labeling scheme accommodating arbitrary labels, including those not generated by the scheme itself.

1. Introduction

Distributed systems have become an integral part of virtually all computing systems, especially those of a large scale. These systems must provide high availability and reliability in the presence of failures, which could be either permanent or transient. A core abstraction for many distributed algorithms simulates shared memory [3]; this abstraction allows to take algorithms designed for shared memory, and port them to asynchronous message-passing systems, even in the presence of failures. There has been significant work on creating such simulations, under various types of permanent failures, as well as on exploiting this abstraction in order to derive algorithms for message-passing systems. (See a recent survey [2].)

All these works, however, only consider permanent failures, neglecting to incorporate mechanisms for handling transient failures. Such failures may result from incorrect initialization of the system, or from temporary violations of the

assumptions made by the system designer, for example the assumption that a corrupted message is always identified by an error detection code. The ability to automatically resume normal operation following transient failures, namely to be self-stabilizing [10], is an essential property that should be integrated into the design and implementation of systems.

Self-stabilizing simulation of a single-writer single-reader atomic shared register in a message-passing system was presented in [14]. This simulation does not tolerate processor crashes. More recent papers [13,21] focused on self-stabilizing simulation of shared registers from weaker shared registers. Self-stabilizing timestamp implementations using SWMR atomic registers were suggested in [1,15]. These simulations already assume the existence of a shared memory, while in contrast, we simulate a shared SWMR atomic register in a message-passing system.

Our contribution This paper presents a practically stabilizing simulation of an atomic register in asynchronous message-passing systems where a minority of processors may crash. The simulation is based on reads and writes to a (majority) quorum in a system with a fully connected graph topology. A key component of the simulation is a new bounded labeling scheme that needs no initialization, as well as a method for using it when communication links and processes are started at an arbitrary state. To the best of our knowledge, our scheme is the first constructive labeling scheme presenting the above properties.

2. Preliminaries

A message-passing system consists of \( n \) processors, \( p_0, p_1, p_2, \ldots, p_{n-1} \), connected by communication links through which messages are sent and received. We assume that the underlying communication graph is completely connected, namely, every pair of processors, \( p_i \) and \( p_j \), have a communication link of bounded capacity \( c \).

A processor is modeled as a state machine that executes steps. In each step, the processor changes its state, and executes a single communication operation, which is either a send message operation or a receive message operation. The communication operation changes the state of an attached link, in the obvious manner.

The system configuration is a vector of \( n \) states, a state for each processor and \( 2(n^2 - n) \) queues, each bounded by a constant capacity \( c \). A set \( s_{ij} \) (rather than a queue, reflects the non-FIFO nature) for each directed edge \( (i, j) \) from a processor \( p_i \) to a processor \( p_j \). Note that in the scope of self-stabilization, where the system copes with an arbitrary starting configuration, there is no deterministic data-link simulation that uses bounded memory when the capacity of links is unbounded [14]. Note further that non-FIFO communication links can be accommodated by mimicking FIFO delivery [11].

An execution is a sequence of configurations and steps, \( E = (C_1, a_1, C_2, a_2 \ldots) \) such that \( C_i, i > 1 \), is obtained by applying \( a_{i-1} \) to \( C_{i-1} \), where \( a_{i-1} \) is a step of a single processor, \( p_j \), in the system. Thus, the vector of states, except the state of \( p_j \), in \( C_{i-1} \) and \( C_i \) are identical. If the single communication operation in \( a_{i-1} \) is a send operation from \( p_j \) to processor \( p_k \), then \( s_{jk} \) in \( C_i \) is obtained from \( s_{jk} \) in \( C_{i-1} \) by enqueuing the message sent in \( a_{i-1} \). If the resulting queue \( s_{jk} \) exceeds its size, i.e., \( |s_{jk}| = c \), then an arbitrary message is deleted from \( s_{jk} \). The rest of the message queues are unchanged. If the single communication operation in \( a_{i-1} \) is a receive operation of a (non-null) message \( M \), then \( M \) (which is the first message to be dequeued from \( s_{ij} \) in \( C_{i-1} \)) is removed from \( s_{ij} \), all the other queues are unchanged. A receive operation by \( p_j \) from \( p_k \) may result in a null message even when the \( s_{ij} \) is not empty, thus allowing unbounded delay for any particular message.

Message losses are modeled by allowing spontaneous message removals from (any place in) the queue. An edge \( (i, j) \) is operational if a message sent infinitely often by \( p_i \) is received infinitely often by \( p_j \).

Atomic register For the simulation of a single writer multi-reader (SWMR) atomic register, we assume \( p_0 \) is the writer and \( p_1, p_2, \ldots, p_{n-1} \) are the readers. There is a procedure for executing a write operation by \( p_0 \), and procedures for executing read operations by the readers.

Each invocation of a read or write operation translates into a sequence of computation steps, following the appropriate procedure. Concurrent invocations of read and write operations yield an execution in which the computation steps corresponding to invocations by different processors are interleaved. An operation \( op_1 \) precedes an operation \( op_2 \) in this execution, if \( op_1 \) returns before \( op_2 \) is invoked. Two operations overlap if neither of them precedes the other.

Each interleaved execution of an atomic register is required to be atomic, namely, equivalent to an execution in which the operations are executed sequentially and the order of non-overlapping operations is preserved [4]. As advocated in [7], the above definition is equivalent to saying that the atomic register has to satisfy the following two properties:

- **Regularity.** A read operation returns either the value written by the most recent write operation that completes before the read, or a value written by a concurrent write.
- **No new/old inversions.** If a read operation \( R \) returns the value of a concurrent write operation \( W \), then no read operation that is started after \( R \) completes, returns the value of a write operation that completes before \( W \) starts.

Practically stabilizing atomic register. A message passing system that simulates an atomic register is an \( r \)-practically stabilizing, if there exists an integer \( r' > r \), such that every execution with \( r' \) write operations has a segment of execution (fragment) with \( r \) write operations that satisfies the atomicity requirements. In particular, a large \( r \) implies the existence of a long segment with the desired behavior. In the sequel, when no confusion is possible, we refer to \( r \)-practically stabilizing simply as practically stabilizing.
Practically stabilizing is reminiscent of pseudo-stabilization [10]. In pseudo-stabilization the length of the suffix of execution where the specification is satisfied is infinite while in practically-stabilizing the system reaches an execution segment that is “almost” (or practically) infinite (for any existing system, where the life of the system is no more than, say the time required by the system to perform $2^{64}$ computer steps) in which the specification is satisfied.

3. Overview of our simulation

Attiya, Bar-Noy and Dolev [3] showed how to simulate a single-writer multi-reader (SWMR) atomic register in a message-passing system supporting two procedures, read and write, for accessing the register. This simple simulation is based on a quorum approach: In a write operation, the writer makes sure that a quorum of processors (consisting of a majority of the processors, in its simplest variant) stores its latest value. In a read operation, a reader contacts a quorum of processors, and obtains the latest values they store for the register; in order to ensure that other readers do not miss this value, the reader also makes sure that a quorum stores its return value.

A key ingredient of this scheme is the ability to distinguish between older and newer values of the register; this is achieved by attaching a sequence number to each register value. In its simplest form, the sequence number is an unbounded integer, which is increased whenever the writer generates a new value. This solution is appropriate for an initialized system, which starts in a consistent configuration, in which all sequence numbers are zero, and are only incremented by the writer or forwarded as is by readers. Essentially, a 64-bit sequence number will not wrap around for a number of writes that lasts longer than the life-span of any reasonable system, and therefore regarded as practically infinite.

However, when there are transient failures in the system, as is the case in the context of self-stabilization, the simulation starts at an uninitialized state, where sequence numbers are not necessarily all zero. It is possible that, due to a transient failure, the sequence numbers hold maximal values when the simulation starts running, and thus will wrap around very quickly. Traditionally, techniques like distributed reset [5,6] are used to overcome this problem. However, in asynchronous crash-prone environments the reset may not terminate waiting for the crashed processes to participate. Hence, a reset invocation will not ensure that the sequence numbers are set to zero.

Our solution is to partition the execution of the simulation into epochs (see Section 4.3), namely periods during which the sequence numbers are supposed to not wrap around. Whenever a “corrupted” sequence number is discovered, a new epoch is started, overriding all previous epochs; this repeats until no more corrupted sequence numbers are hidden in the system, and the system stabilizes. In a steady state, after the system stabilizes, it remains in the same epoch (at least until the sequence numbers wrap around, which is essentially unlikely to happen).

This raises naturally, the question of identifying epochs. The natural idea of using integers, is bound to run into the same problems as per the sequence numbers. Instead, we use a bounded labeling scheme [16,20] for the epochs; this is a function for generating labels (in a bounded domain), that guarantees that two labels can be compared to determine the largest among them. Existing labeling schemes however, assume that labels have specific initial values, and that new labels are introduced only by means of the label generation function. In contrast, transient failures, of the kind the self-stabilizing simulation must withstand, can create incomparable labels, so it is impossible to tell which is the largest among them or to pick a new label that is bigger than all of them.

To address this difficulty, we introduce a bounded labeling scheme (see Section 4.2) that allows to define a label larger than any set of labels, provided that its size is bounded. We assume links have bounded capacity, and hence the number of epoch labels initially hidden in the system is bounded.

The writer tracks the set of epoch labels it has seen recently; whenever the writer discovers that its current epoch label is not the largest, or is incomparable to some existing epoch label, the writer generates a new epoch that is larger than all the epochs it has. The number of bits required to represent an epoch label depends on $m$, the maximal size of the set, and it is in $O(m \log m)$. We ensure that the size of the set is proportional to the total capacity of the communication links, namely $O(cn^2)$, where $c$ is the bound on the capacity of each link (expressed in number of messages) and $n$ is the number of processors, hence each epoch label requires $O(cn^2 \log n + \log c)$ bits.

It is possible to reduce this complexity making $c$ constant, using a self-stabilizing data-link protocol for communication among the processors for bounded capacity links over FIFO and non-FIFO communication links [11,17].

We show that after a bounded number of write operations, the results of reads and writes can be totally ordered in a manner that respects the real-time order of non-overlapping operations, so that the sequence of operations satisfies the semantics of an SWMR register. This holds until the sequence numbers wrap around, as can happen when the unbounded simulation of [3] is deployed in realistic systems, where all values are bounded.

Note that the original design of [3] copes with non-FIFO and unreliable links. We assume that our atomic register simulation runs on top of an optimal stabilizing data-link layer that emulates a reliable FIFO communication channel over unreliable capacity bounded non-FIFO channels [11].

\[\text{Note that these protocols are also snap-stabilizing--starting in an arbitrary configuration, the first invoked send operation succeeds to deliver the message.}\]
4. Tool box

4.1. The basic quorum-based simulation

We describe below the basic simulation, which follows the quorum-based approach of [3], and ensures that our algorithm tolerates (crash) failures of a minority of the processors.

The simulation relies on a set of read and write quorums, each being a majority of processors. The simulation specifies the write and read procedures, in terms of QuorumRead and QuorumWrite operations. The QuorumRead procedure sends a request to every processor, for reading a certain local variable of the processor; the procedure terminates with the obtained values, after receiving answers from processors that form a quorum. Similarly, the QuorumWrite procedure sends a value to every processor to be written to a certain local variable of the processor; it terminates when acknowledgments from a quorum are received. If a processor that is inside QuorumRead or QuorumWrite keeps taking steps, then the procedure terminates (possibly with arbitrary values). Furthermore, if a processor starts QuorumRead procedure execution, then the stabilizing data link [17,18] ensures that a read of a value returns a value held by the read variable some time during its period; similarly, a QuorumWrite(v) procedure execution, causes v to be written to the variable during its period.

Each processor pi maintains a variable, MaxSeqi, supposed to be the “largest” sequence number the processor has read, and a value vi, associated with MaxSeqi, which is supposed to be the value of the implemented register.

The write procedure of a value v starts with a QuorumRead of the MaxSeqi variables; upon receiving answers l1, l2, . . . from a quorum, the writer picks a sequence number lm that is larger than MaxSeq0 and l1, l2, . . . by one; the writer assigns lm to MaxSeqi and calls QuorumWrite with the value (lm, v). Whenever a quorum member pi receives a QuorumWrite request (l, v) for which l is larger than MaxSeqi, pi assigns l to MaxSeqi and v to vi.

The read procedure by pi starts with a QuorumRead of both the MaxSeqj and the (associated) vj variables. When pi receives answers (l1, v1), (l2, v2) . . . from a quorum, pi finds the largest epoch label lm among MaxSeqi, and l1, l2, . . . and then calls QuorumWrite with the value (lm, vm). This ensures that later read operations will return this, or a later value of the register. When QuorumWrite terminates, after a write quorum acknowledges, pi assigns lm to MaxSeqi and vm to vi, and returns vm as the value read from the register.

Note that the QuorumRead operation, beginning the write procedure of p0, helps to ensure that MaxSeqi holds the maximal value, as the writer reads the biggest accessible value (directly read by the writer, or propagated to a quorum that will be later read by the writer) in the system during any write.

Let g(C) be the number of distinct values greater than MaxSeq0 that are accessible in some configuration C, and let C1, C2, . . . be the configurations in the execution. Since all the processors, except the writer, only copy values and since p0 can only increment the value of MaxSeq0, it holds for every i ≥ 1 that

\[ g(C_i) ≥ g(C_{i+1}). \]

Furthermore,

\[ g(C_i) > g(C_{i+1}), \]

whenever the writer discovers (when executing step ai) a value greater than MaxSeq0. Roughly speaking, the faster the writer discovers these values, the earlier the system stabilizes. If the writer does not discover such a value, then the accessible portion of the system in which its values are repeatedly written, performs reads and writes correctly.

4.2. A bounded labeling scheme with uninitialized values

Let k > 1 be an integer, and let K = k^2 + 1. We consider the set X = {1, 2, ..., K} and let L (the set of labels) be the set of all ordered pairs (s, A) where s ∈ X is called in the sequel the Sting of the label, and A ⊆ X has size k and is called in the sequel the Antistings of the label. It follows that |L| = (\binom{K}{k})K = k^{k+1}\cdot 1^k.

The comparison operator <_0 among the bounded labels is defined to be:

\[ (s_j, A_j) <_0 (s_i, A_i) \iff (s_j \in A_i) \land (s_i \notin A_j). \]

Note that this operator is antisymmetric by definition, yet may not be defined for every pair (s_i, A_i) and (s_j, A_j) in L (e.g., s_j \in A_i and s_i \in A_j).

We define now a function to compute, given a subset S of at most k labels of L, a new label which is greater (with respect to <_0) than every label of S. This function, called NextS (see the left side of Fig. 1) is as follows. Given a subset of k labels (s_1, A_1), (s_2, A_2), . . . , (s_k, A_k), we take a label (s_i, A_i) that satisfies:

- s_i is an element of X that is not in the union A_1 ∪ A_2 ∪ . . . ∪ A_k (as the size of each A_s is k, the size of the union is at most k^2, and since X is of size k^2 + 1 such an s_i always exists).

---

2 Standard end-to-end schemes [19] can be used to implement the quorum operation in the case of general communication graph.
Next$_b$

input: $S = (s_1, A_1), (s_2, A_2), \ldots, (s_k, A_k)$; labels set
function: For any $\emptyset \neq S \subseteq X$, pick$(S)$ returns arbitrary
(later defined for particular cases) element of $S$
1: $A := [s_1] \cup [s_2] \cup \ldots \cup [s_k]$
2: while $A \neq k$
3: $A := A \cup \{\text{pick}(X \setminus A)\}$
4: $s := \text{pick}(X \setminus (\{A_1 \cup A_2 \cup \ldots \cup A_k\}))$
5: return $(s, A)$

Next$_e$

input: $S$: set of $k$ timestamps
output: $(l, i)$: timestamp
1: if $3(b_0, j_0) \in S$ such that $\forall (l, j) \in S, (l, j) \neq (b_0, j_0),$
   $(l, j) \prec (b_0, j_0) \land j_0 < r$
2: then return $(b_0, j_0 + 1)$
3: else return $(\text{Next}_b(S), 0)$

Fig. 1. Next$_b$ and Next$_e$. $\hat{S}$ is the set of labels appearing in $S$.

- $A_i$ is a subset of size $k$ of $X$ containing all values $(s_1, s_2, \ldots, s_k)$ (if they are not pairwise distinct, add arbitrary elements of $X$ to get a set of size exactly $k$).

It is simple to compute $A_i$ and $s_j$, given a set $S$ with $k$ labels, and can be done in time linear in the total length of the labels given, i.e., in $O(k^2)$ time.

Lemma 1. Given a subset $S$ of $k$ labels from $L$, $(s_j, A_i) = \text{Next}_b(S)$ satisfies:

$\forall (s_j, A_j) \in S, (s_j, A_j) \prec_b (s_1, A_i)$.

Proof. Let $(s_j, A_j)$ be an element of $S$. By construction, $s_j \in A_i$ and $s_j \not\in A_j$, and the result follows from the definition of $\prec_b$. $\square$

For example, consider the case in which $k = 4$, $K = 17$, and the following five arbitrary labels $(2, (1, 5, 17, 4))$ (where 2
is the sting and $(1, 5, 17, 4)$ is the set of antistings of this first label), $(12, (16, 7, 11, 3)), (5, (8, 10, 2, 5)), (10, (12, 13, 9, 2))$. Then there must exist a value in the 17 possible values (as $K = 17$) that is not equal to any antisting, in our example, $6, 14, 15$ are not equal to any antistings in the list $1, 5, 17, 4, 16, 7, 11, 3, 8, 10, 2, 5, 12, 13, 9, 2$ (note that the list includes 5 and 2 twice). Thus, when constructing a label greater than the given five labels, it is possible to choose any one of the numbers $6, 14, 15$ to be a sting, while the antistings list of the constructed larger label must be a superset (of size four) of the stings of the given arbitrary labels, in our case, we must have $(2, 12, 5, 10)$. The result is the label $(6, (2, 12, 5, 10))$ which is greater than any label of the given arbitrary set.

4.3. Timestamps and epochs

Each value (written or read on the emulated register) is tagged with a timestamp—a pair $(l, i)$ where $l$ is an epoch (a bounded label generated via the bounded scheme described in Section 4.2), and $i$ is a sequence number, an integer between 0 and a fixed bound $r \geq 1$.

As described in the overview section, it is possible that the sequence numbers wrap around faster than planned, due to “corrupted” initial values. When the writer discovers that this has happened, it opens a new epoch.

Epochs are denoted with labels from a bounded domain, using a bounded labeling scheme (see Section 4.2). Such a scheme provides a function to compute a new label, which is “larger” than any given set of labels.

Definition 1. A labeling scheme over a bounded domain $L$, provides an antisymmetric comparison predicate $\prec_b$ on $L$ and a function Next$_b(S)$ that returns a label in $L$, given some subset $S \subseteq L$ of size at most $m$. It is guaranteed that for every $L \in S$, $L \prec_b \text{Next}_b(S)$.

Note that the labeling scheme of [20], used in the original atomic memory simulation [3], cannot cope with transient failures. Section 4.2 describes a bounded labeling scheme that accommodates badly initialized labels, namely, those not generated by using Next$_b$.

This scheme ensures that if the writer eventually learns about all the epoch labels in the system, it will generate an epoch label greater than all of them. After this point, any read that starts after a write of $\nu$ is completed (written to a quorum) returns $\nu$ (or a later value), since the writer will use increasing sequence numbers. The eventual convergence of the labeling scheme depends on invoking Next$_b$ with a parameter $S$ that is a superset of the epoch labels in the system.

The Next$_e$ operator compares between two timestamps, and is described in the right part of Fig. 1. Note that in Line 3 of the code we use $\hat{S}$ for the set of labels (with sequence numbers removed) that appear in $S$. The comparison operator $\prec_e$ for timestamps is:
\((x, i) \prec_e (y, j) \equiv x \prec_b y \lor (x = y \land i < j)\).

In the sequel, we use \(\prec_b\) to compare timestamps only by their labels (ignoring their sequence numbers).

4.4. Guessing game

The difficulty in emulating an atomic register in stabilizing settings comes mainly from the difficulty of the writer process to timestamp the new introduced value with a timestamp that is guaranteed to be greater than any timestamp used for the previous values. We explain the intuition of this part of the simulation through the following two-player guessing game, between a finder, representing the writer, and a hider, representing an adversary controlling the system. Note that the part of the timestamp that creates problems is the epoch which is a bounded label. Therefore, we project the guessing game on the label part of the timestamp. The distributed implementation of writer strategy in this guessing game is presented in details in the next section.

- The hider maintains a set of labels \(\mathcal{H}\), whose size is at most \(m\) (a parameter fixed later).
- The finder does not know \(\mathcal{H}\), but it needs to generate a label greater than all labels in \(\mathcal{H}\).
- The finder generates a label \(L\) and if \(\mathcal{H}\) contains a label \(L'\), such that it does not hold that \(L' \prec_b L\) then the hider exposes \(L'\) to the finder.
- In this case, the hider may choose to add \(L\) to \(\mathcal{H}\), however, it must ensure that the size of \(\mathcal{H}\) remains at most \(m\), by removing another label. (The finder is unaware of the hider’s decision.)
- If the hider does not expose a new label \(L'\) from \(\mathcal{H}\), the finder wins this iteration and continues to use \(L\).

The strategy of the finder is based on maintaining an FIFO queue of \(2m\) labels, meant to track the most recent labels. The queue starts with arbitrary values, and during the course of the game, it holds up to \(m\) recent labels produced by the finder, which turned out to be overruled by existing labels (provided by the hider). The queue also holds up to \(m\) labels that were revealed to overrule these labels.

Before the finder chooses a new label, it enqueues its previously chosen label and the label received from the hider in response. Enqueuing a label that is already in the queue pushes the label to the front of the queue; if the bound on the size of the queue is reached, then the oldest label in the queue is dequeued. This semantics of enqueue is used throughout the paper.

The finder chooses the next label by applying \textbf{Next}, using as parameter the \(2m\) labels in the queue. Intuitively, the queue eventually contains a superset of \(\mathcal{H}\), and the finder generates a label greater than all the current labels of the hider.

Clearly, when the finder chooses the \(i\)th label, \(i > 0\), the \(2i\) items in the front of the queue consist of the first \(i\) labels generated by the finder, and the first \(i\) labels revealed by the hider. This is used to show the following property of the game.

\textbf{Lemma 2.} After at most \(m + 1\) labels, the finder generates a label that is larger than all the labels held by the hider.

\textbf{Proof.} Note that a response cannot expose a label that has been introduced or previously exposed in the game since the finder always chooses a label greater than all labels in the queue. Thus, if the finder does not win when introducing the \(m\)th label, all the \(m\) labels that the hider had when the game started were exposed and therefore, stored in the queue of the finder together with all the recent \(m\) labels introduced by the finder, before the \(m + 1\)st label is chosen. Thus, the \(m + 1\)st label is larger than every label held by the hider, and the finder wins. \(\square\)

Note that a step of the hider that exposes more than one label unknown to the finder, accelerates the convergence to a winning stage.

5. Putting the pieces together

Each processor \(p_i\), holds, in \textit{MaxTS}\(_i\), two fields \(\langle ml_i, cl_i\rangle\), where \(ml_i\) is the timestamp associated with the last write of a value to the variable \(v_i\) and \(cl_i\) is a canceling timestamp possibly empty \((\bot)\), which is not smaller than \(ml_i\) in the \(\prec_b\) order. The canceling field is used to let the writer (finder in the game) know an evidence on the existence of the unknown (non-smaller) epoch label. A timestamp \((l, i)\) is evidence for timestamp \((l', j)\) if and only if \(l \neq_b l'\). When the writer faces an evidence it changes the current epoch label.

The pseudo code for the read and write procedures appears in Fig. 2. Note that in Lines 2 and 10 of the write procedure, an epoch label is enqueued if and only if it is not equal to \textit{MaxTS}0. Note further, that \textit{Next} in Line 5 of the write procedure, first tries to increment the sequence number of the epoch label in \textit{MaxTS}0 and if the sequence number already equals to the upper bound \(r\) then \(p_0\) enqueues the value of \textit{MaxTS}0 and uses the updated epochs queue to choose a new value for \textit{MaxTS}0, which is a new epoch label \textit{Next}0(epochs) and sequence number 0.

The write of a value \(v\) starts with a Quorum\textit{Read} of the \textit{MaxTS}\(_i\) variables, and upon receiving answers \(l_1, l_2, \ldots\) from a quorum, the writer \(p_0\) enqueues the epoch labels of the received \(ml\) and non-\(\bot\) \(cl\) which are not equal to \textit{MaxTS}0, to the epochs queue (Lines 1–3). The writer then computes \textit{MaxTS}0 to be the \textit{Next} timestamp, namely if the epoch label of \textit{MaxTS}0 is the largest in the epochs queue and the sequence number of \textit{MaxTS}0 less than \(r\), then \(p_0\) increments the
sequence number of $MaxTS_0$ by one, leaving the epoch label of $MaxTS_0$ unchanged (Lines 4–5). Otherwise, it is necessary to change the epoch label: $p_0$ enqueues $MaxTS_0$ to the $epochs$ queue and applies $NextTS$ to obtain an epoch label greater than all the ones in the $epochs$ queue; it assigns to $MaxTS_0$ the timestamp made of this epoch label and a zero sequence number (Lines 7–8). Finally, $p_0$ executes the $QuorumWrite$ procedure with ($MaxTS_0$, $v$) (Line 9).

Whenever the writer $p_0$ receives (as a quorum member) a $QuorumWrite$ request containing an epoch label that is not equal to $MaxTS_0$, $p_0$ enqueues the received epoch label in the $epochs$ queue (Line 10). (Recall the rules for enqueuing the queue from Section 4.3.)

The read of a reader $p_i$ starts with a $QuorumRead$ of the $MaxTS_j$ and the (associated) $v_j$ variables (Line 1). When $p_i$ receives answers $\langle ml_1, cl_1, v_1 \rangle$, $\langle ml_2, cl_2, v_2 \rangle, \ldots$ from a quorum, $p_i$ tries to find a maximal timestamp $ml_m$ according to the $\prec$ operator from among $ml_1, cl_1, ml_2, cl_2, \ldots$. If $p_i$ finds such maximal timestamp $ml_m$, then $p_i$ executes the $QuorumWrite$ procedure with ($ml_m, v_m$). Once the $QuorumWrite$ terminates (the members of a quorum acknowledged) $p_i$ assigns $MaxTS_i := (ml_m, \perp)$, and $v_i := v_m$ and returns $v_m$ as the value read from the register (Lines 2–5). Otherwise, in case no such maximal value $ml_m$ exists, the read is aborted (Line 6).

When a quorum member $p_i$ receives a $QuorumWrite$ request $\langle l, v \rangle$, it checks whether both $MaxTS_j, ml \prec_l l$ and $MaxTS_i, cl \prec_l l$. If this is the case, then $p_i$ assigns $MaxTS_i := (l, \perp)$ and $v_i := v$ (Lines 7–9). Otherwise, $p_i$ checks whether $l \neq b MaxTS_i, ml$ and if so assigns $MaxTS_i, cl := l$ (Line 10). Note that $\perp \prec_l l$, for any $l$.

### Diffusing labels over the data-link

Note that we assume an underlying stabilizing data-link protocol [10,17]. The data-link protocol is used for repeatedly diffusing the value of $MaxTS$ from one processor to another. If the $MaxTS_i, cl$ of a processor $p_i$ is $\perp$ and $p_i$ receives from processor $p_j$ a $MaxTS_j$ such that $MaxTS_j, ml \neq b MaxTS_i, ml$ then $p_i$ assigns $MaxTS_i, cl := MaxTS_j, ml$. Otherwise, $MaxTS_i, cl \neq b MaxTS_j, ml$ then $p_i$ assigns $MaxTS_i, cl := MaxTS_j, cl$. Note also that the writer will enqueue every diffused value that is different from $MaxTS_0, ml$ (similarly to lines 10 of the reader and the writer, where each of $MaxTS_i, ml$ and $MaxTS_i, cl$ are considered $l$).

### 6. Correctness proof

#### Overview of the correctness proof

The correctness of the simulation is implied by the game and our previous observations, which we can now summarize, recapitulating the arguments explained in the description of the individual components. Note that the writer may enqueue several unknown epochs in a single write operation and only then introduce a greater epoch, such a scenario will result in a shorter winning strategy in the game as the writer gains more knowledge concerning the existing (hidden) labels before introducing a new epoch.

In the simulation, the finder/writer may introduce new epoch labels even when the hider does not introduce an evidence. We consider a timestamp $(l, i)$ to be an evidence for timestamp $(l', j)$ if and only if $l \neq b l'$. Using a large enough bound $r$ on the epoch number, we ensure that either there is an execution with $r$ writes in which the finder/writer introduces new timestamps with no epoch label change, and therefore with growing sequence numbers, and well-defined timestamp ordering, or a new epoch label is frequently introduced due to the exposure of hidden unknown epoch labels. The last case follows the winning strategy described for the game.

The sequence numbers allow the writer to introduce many timestamps, exponential in the number of bits used to represent $r$, without storing all of them, as their epoch label is identical. The sequence numbers are a simple extension of the bounded epoch labels just as a least significant digit of a counter; this allows the queues to be proportional to the bounded number of the epoch labels in the system. Thus, either the writer introduces an epoch label greater than anyone in the system, and hence will use this epoch label to essentially implement a register for an execution of $r$ writes, or the readers never introduce some existing bigger epoch label letting the writer increment the sequence number practically
Proof. Let \( E \) be an execution with \( r(m + 2) \) writes. Following Lemmas 3 and 4, \( E \) contains an execution \( E' \) with \( r \) writes, where any read returns a non-abort value and any write includes in its decision the set of all the accessible epoch labels in the system. Assume there is a process \( p \) such that the read invocations of \( p \) always return an obsolete value. That is, the value returned by the read is either a hidden value or a value corresponding to a previous write but not the most recent. Let \( R \) be such a read. In \( E' \), \( R \) returns the output value with the maximum timestamp over the set of epoch labels returned by QuorumRead. Let \( W_1 \) and \( W_2 \) be two write operations such that \( W_1 \) completes before \( W_2 \) and \( R \). Since \( W_1 \) completes before \( R \) then the epoch label computed by \( W_1 \) is written in at least a majority of processes via a QuorumRead and is greater than any epoch label in the system. When \( R \) starts invoking QuorumRead two cases may appear: (1) \( W_2 \) did not modify the value written by \( W_1 \) and did not start its promotion via QuorumWrite or (2) \( W_2 \) executes QuorumWrite but did not finish its execution. In the first case, \( W_1 \)'s MaxTS is the largest in the accessible system. When \( R \) invokes the QuorumRead it gets \( W_1 \)'s MaxTS value (otherwise \( W_1 \) is not terminated) and returns it. Hence, \( R \) cannot return a value older than the one written by \( W_1 \). In the second case, some processes contacted in the QuorumRead may send the \( W_1 \)'s
MaxTS, other processes may send $W_2$'s MaxTS. Since the MaxTS computation at the writer is sequential then $W_2$'s MaxTS is greater than $W_1$'s MaxTS. In such a case, by Lines 2 and 3 in the reader code, $R$ should return $W_2$'s MaxTS. Hence, $R$ will return the last written value.

**Lemma 6.** Every execution with $r(m + 2)$ writes has an execution with $r$ writes in which the no new/old inversion property is respected.

**Proof.** Let $E$ be an execution with $r(m + 2)$ writes. Following Lemmas 3 and 4, $E$ contains an execution with $r$ writes, $E'$, where any read does not return abort. In the following we prove that $E'$ does not violate the new/old inversion property. Consider two write operations $W_1$ and $W_2$ in $E'$ such that $W_1$ completes before $W_2$. Consider also two read operations $R_1$ and $R_2$ such that $R_1$ completes before $R_2$ and $W_1$ completes before $R_1$. Assume $R_1$ and $R_2$ overlap $W_2$. Assume a new/old inversion happens and $R_1$ returns the value written by $W_2$. Denote the MaxTS of $W_2$ by $I_2$. Assume also $R_2$ returns the value written by $W_1$ which MaxTS is $I_1$. Since $R_1$ completes before $R_2$ then before the start of $R_2$, $R_1$ executes the following actions: it modifies its MaxTS to $I_2$, it also executes QuorumWrite in order to inform the system of its new value. Since QuorumWrite returns before $R_1$ finishes then $I_2$ is already adopted by at least a majority of processes. That is, since $I_2 \succ I_1$ ($W_1$ completes before $W_2$), then $I_2$ replaces $I_1$ in at least a majority of processes.

We assumed $R_2$ returns $I_1$. Since $R_1$ completes before $R_2$ then $R_2$ starts its QuorumRead after $R_1$ returned so after $R_1$ completed its QuorumWrite operation. This implies that $I_2$ is the epoch label adopted by at least a majority of processes and at least one process in this majority will respond while $R_2$ invokes its QuorumRead. That is, $R_2$ collects at least one epoch label $I_2$ and since $I_2 \succ I_1$, $R_2$ should return this value. This contradicts the assumption $R_2$ returns $I_1$. It follows that $E'$ respects the no new/old inversion property.

The main theorem follows directly from Lemmas 5 and 6.

**Theorem 1.** The algorithm satisfies the practically stabilizing SWMR atomic memory specification.

7. Discussion

We have presented a self-stabilizing simulation of a single-writer multi-reader atomic register, in an asynchronous message-passing system in which at most half the processors may crash.

Given our simulation, it is possible to realize a self-stabilizing replicated state machine [22]. The self-stabilizing consensus algorithm presented in [15] uses SWMR registers, and our simulation allows to port them to message-passing systems. More generally, our simulation allows the application of any self-stabilizing algorithm that is designed using SWMR registers to work in a message-passing system, where less than the majority of the processors may crash.

One restriction of such implementation is that the writer does not stop writing prematurely (before the SWMR register stabilizes and starts to return a consistent value). Following our work the authors of [12] suggest a pseudo stabilizing implementation in which the writer has a major responsibility, namely, the writer has to complete updating the last value, unlike our solution here where readers assist each other to spread the most up-to-date value using the epoch based technique.

Furthermore, a much more complicated and expensive technique in terms of communication and memory is used as part of the directly implemented self-stabilizing Paxos [8] in which writers may stop writing.
